We show how engineered classical noise can be used to generate constrained Hamiltonian dynamics in atomic quantum simulators of many-body systems, taking advantage of the continuous Zeno effect. After discussing the general theoretical framework, we focus on applications in the context of lattice gauge theories, where imposing exotic, quasi-local constraints is usually challenging. We demonstrate the effectiveness of the scheme for both Abelian and non-Abelian gauge theories, and discuss how engineering dissipative constraints substitutes complicated, non-local interaction patterns by global coupling to laser fields.

PACS numbers: 03.65.Xp,37.10.Jk,11.15.Ha

Laboratory experiments with atomic quantum-degenerate gases have established a synergetic link between atomic physics and condensed matter [1–3], and hold prospects for a similar connection to high-energy physics [4–8, 10–12]. Loaded into optical lattices, cold atoms realize Hubbard models, which can be designed and controlled via external fields to mimic the dynamics of quantum many-body systems in equilibrium and non-equilibrium situations [3, 13]. While a focus of research during the last decade has been the development of a toolbox for designing specific lattice Hamiltonians [1–3], we address below the problem of implementing desired Hubbard dynamics in the presence of constraints, i.e., we wish to keep the system dynamics within a certain subspace of the total Hilbert space. A familiar way of imposing such constraints is to add an energy penalty to the Hamiltonian [14]. Below, we describe an alternative scenario that is based on driving the system with engineered classical noise, exploiting the Zeno effect [15–20]. As we will see, ‘adding noise’ provides a general tool to implement – in an experimentally efficient and accessible way – highly nontrivial constraints in quantum many-body systems.

The present work is motivated by the ongoing quest to build a quantum simulator for Abelian and non-Abelian lattice gauge theories (LGTs) with cold atoms in optical lattices [5–8, 10–12]. LGTs play a prominent role in both particle and condensed matter physics: in the standard model, the interaction between constituents of matter are mediated by gauge bosons [21–24], and in frustrated magnetism, quantum spin liquids are suitably described in the language of gauge theories [14, 25, 26]. The key feature of a LGT is the presence of local (gauge) symmetries. The generators \( G_x^a \) of these local gauge transformations, with \( x \) denoting lattice sites and \( a \) a color index, commute with the lattice Hamiltonian, \( [H_0,G_x^a] = 0 \) for all \( x,a \), and thus provide local conservation laws. They have the meaning of Gauss’s laws, as they constrain the dynamics of the system to a physical subspace \( \mathcal{H}_P \) given by the constraints \( G_x^a|\psi\rangle = 0 \) [27]. In high-energy physics, gauge symmetries are from fundamental considerations exact, but in quantum simulations these symmetries will normally be approximate on some level in the microscopic model. Thus, the microscopic Hamiltonian will be of the form \( H_{\text{micro}} = H_0 + H_1 \), with \( H_0 \sim J \) the desired gauge-invariant part, and \( H_1 \sim \lambda \) a perturbation, which drives the system dynamics outside of the gauge-invariant subspace \( \mathcal{H}_P \), see Fig. 1(a). A central challenge of quantum simulating LGTs is to introduce mechanisms that suppress these errors.

**Gauge constraints via classical noise.** A common strategy to restrict the dynamics to a certain subspace is by adding an energy penalty to the microscopic Hamiltonian: \( H_{\text{micro}} = H_0 + H_1 + H_U \), with \( H_U \sim U \gg \lambda \). In this case, to order \( \lambda^2/U \), manifolds with different eigenvalues of \( H_U \) become decoupled. In the context of LGTs, one can use \( H_U = U \sum_x (G_x^a)^2 \) to impose the Gauss law constraints [5, 7, 10, 14, 28, 29]. Since in a LGT the gen-

---

* Equal contribution.
operators \( G_x^a \) are complicated expressions of the matter and gauge fields – especially in non-Abelian models – adding an interaction term involving the square of these poses a formidable challenge [30]. In contrast, we pursue here the strategy of enforcing the constraints \( G_x^a |\psi\rangle = 0 \) by adding classical noise terms to the microscopic Hamiltonian

\[
H_{\text{micro}}(t) = H_0 + H_1 + \sqrt{2\kappa} \sum_{x,a} \xi_x^a(t) G_x^a, \tag{1}
\]

which are linear in \( G_x^a \) and involve independent white-noise processes \( \xi_x^a(t) \) with \( \langle \xi_x^a(t) \xi_y^b(t') \rangle = \delta_{xy} \delta_{ab} \delta(t - t') \). Each realization of the noise will give rise to an evolution of the system described by a stochastic state vector \( |\psi(t)\rangle \). Averaging over the noise fluctuations leads to the density operator \( \rho = \langle |\psi(t)\rangle \langle \psi(t)| \rangle \), obeying the master equation (see supplemental material [31])

\[
\dot{\rho} = -i H_{\text{eff}} \rho + i \rho H_{\text{eff}}^\dagger + 2\kappa \sum_{x,a} G_x^a \rho G_x^a^\dagger, \tag{2}
\]

with non-Hermitian Hamiltonian \( H_{\text{eff}} \),

\[
H_{\text{eff}} = H_0 + H_1 - i \kappa \sum_{x,a} (G_x^a)^2.
\]

The effective Hamiltonian \( H_{\text{eff}} \) contains a damping term involving the square of the generators, introduced by the noisy single-particle terms in Hamiltonian (1). For \( \kappa/\lambda \gg 1 \), this term constrains the evolution to \( \mathcal{H}_P \). In fact, this scale separation of a large rate vs. a small energy scale provides the dissipative analogue of the energetic protection described above, which relies on the separation of two energy scales. In the present case, the protection term arises from a linear coupling of the generators to a classical noise source, which – in contrast to an energy penalty \( H_U \) – does not require complicated, non-local two-body interactions.

To demonstrate the dissipative protection explicitly, we integrate out the dynamics of the gauge-variant space \( \mathcal{H}_Q \), defined by \( G_x^a |\psi\rangle \neq 0 \), to leading order in \( \lambda/\kappa \). Denoting by \( \mathcal{P} \) the projector on \( \mathcal{H}_P \), we obtain the following master equation for the gauge-invariant part of the density operator \( \rho_{PP} = \mathcal{P}_\rho \mathcal{P} \)

\[
\dot{\rho}_{PP} = -i \tilde{H}_{\text{eff}} \rho_{PP} + i \rho_{PP} \tilde{H}_{\text{eff}}^\dagger,
\]

with effective non-Hermitian Hamiltonian

\[
\tilde{H}_{\text{eff}} \approx \mathcal{P}(H_0 + H_1)\mathcal{P} - i \mathcal{P} H_1 Q \frac{1}{\kappa \sum_{x,a} (G_x^a)^2} Q H_1 \mathcal{P}, \tag{3}
\]

where \( Q = \mathcal{1} - \mathcal{P} [31] \). Starting from an initial state \( |\psi_0\rangle \in \mathcal{H}_P \), the evolution under this Hamiltonian is restricted to \( \mathcal{H}_P \), but reduces the norm of the state vector, signifying the transfer of population to the gauge-variant subspace \( \mathcal{H}_Q \). This population transfer sets a timescale \( t \lesssim \kappa/\lambda^2 \) below which the dissipative protection of local quantities is effective. Therefore, in the strong-noise limit considered in this work, gauge invariance is protected for times long compared to the time scales at which errors accumulate without the engineered noise, \( t \sim 1/\lambda \).

This suppression of transitions by fast classical fluctuations is related to motional narrowing [32, 33], and to dynamical decoupling techniques [34] such as bang-bang control [16, 35], which suppress unwanted couplings to an environment, e.g., in a quantum information context. More specifically, our scheme can be seen as a classical analogue of the quantum Zeno effect [17, 36], which has been discussed in the context of quantum control [18–20], but also of quantum many-body systems [37–40].

**Dissipative protection in Abelian LGTs.** As a first illustrative and conceptually simple example, we demonstrate protection of gauge invariance in a one-dimensional U(1) lattice model, the Schwinger model, whose Hamiltonian takes the form [11]

\[
H_0 = \sum_x [ J(\psi_x^\dagger U_{x,x+1} \psi_{x+1} + \text{h.c.}) + m(-1)^x \psi_x^\dagger \psi_x + \tilde{g}^2 (\psi_x^\dagger \psi_x)^2].
\]

Here, \( \psi_x \) are (staggered) fermionic matter fields defined...
The system dynamics involves states of the form $|\psi\rangle = \psi_x \psi_{x+1}$, where we prepare the system in the ground state $|\psi\rangle_0$ at time $t=0$. The corresponding Gauss law $G_\alpha |\psi\rangle = 0$ is the lattice equivalent of the one of continuum quantum electrodynamics. In the Wilson formulation of LGTs [25, 46], $U_{x,x+1}$ are complex phase variables, but for our purposes the \textit{quantum link model} (QLM) formalism [11, 41–44] is more convenient, where the link variables are represented by spin degrees of freedom, i.e., $U_{x,x+1} = S^x_{x,x+1} E_{x,x+1} = S^z_{x,x+1}$. We choose here a representation using spin-1/2 degrees of freedom, which corresponds to a 1D version of the Schwinger model with a finite electric flux running through the system, also known as finite $\theta$ angle [5, 11]. Despite its simplicity, this model displays various interesting features related to gauge theories, such as confinement and string-breaking phenomena [5, 11].

The system dynamics between two sites as induced by Eq. (4) is sketched in Fig. 2(a-b). On the left-hand side, a typical gauge-invariant state $|\varphi\rangle$ is illustrated, where the Gauss law is satisfied at both vertices. Under the action of the correlated tunneling contained in $H_0$, $\psi_x S^x_{x,x+1} \psi_{x+1}$, the fermion tunnels from $x$ to $x+1$, and the center spin $S^x_{x,x+1}$ flips, preserving gauge invariance in the final state $|\varphi^\prime\rangle$. Processes of this kind describe the creation of a particle-antiparticle pair accompanied by an excitation of the gauge field. In typical implementations, additional gauge-variant imperfections appear, such as single-fermion tunneling $H_1 = \lambda \sum_x (\psi^\dagger_x \psi_{x+1} + \text{h.c.})$. Once such processes are allowed, the system dynamics involves states of the form $|\varphi^\prime\rangle$, where the condition $G_\alpha |\varphi^\prime\rangle = 0$ is not satisfied for all $x$, thus leading to leakage into $H_Q$. Imperfections of this kind correspond to a creation of a particle-antiparticle pair without any effect on the gauge fields, destroying gauge invariance.

To illustrate the dissipative protection in this model, we study quantum-quench dynamics as illustrated in Fig. 2(c-f), where we prepare the system in the ground state of $m = \infty$ and quench to $m = 0$ at time $t = 0$. The system evolves under $H_0$ given by Eq. (4) plus a gauge-variant fermion hopping $H_1$. For $\lambda \neq 0$, gauge invariance is clearly violated and the evolution of observables deviates from the ideal case (red curves in panels (c-e)). Increasing the strength $\kappa$ of the dissipation (green curves) gradually restores the ideal dynamics (blue curves). The expected scaling $\sim 1/\kappa$ of the protection mechanism is confirmed in panel (f). While this example illustrates that the dissipative protection works in principle, we now apply the same mechanism to a more complicated non-Abelian LGT, where enforcing gauge invariance via noise may prove a considerable advantage in the design of an atomic quantum simulator.

\textbf{Dissipative protection in non-Abelian LGTs.} We now illustrate the dissipative protection of gauge invariance for a non-Abelian LGT, namely a U(2) QLM that may be realistically realized in cold-atom experiments (see below). The presence of color (gauge) degrees of freedom allows to investigate in this simplified model physical phenomena related to general non-Abelian gauge theories like QCD, such as chiral symmetry breaking and confinement, and its phase diagram may support exotic condensate phases [10]. Its Hamiltonian, which belongs to a class of more general QLMs including U(N) and SU(N) symmetries, reads $H_0 = H_I + H_m$ [47], where $H_m = m \sum_x (-1)^x \psi^\dagger_x \psi_x$ describes staggered fermions and $H_J$ is the interaction between matter and gauge field

\begin{equation}
H_J = J \sum_x \psi^\dagger_x U_{x,x+1} \psi_{x+1} + \text{h.c.} \equiv J \sum x \psi^\dagger_x \psi_{x+1} + \text{h.c.}
\end{equation}

Here, $\alpha, \beta = 1, 2$ represents the U(2) color degree of freedom (repeated indices are contracted). As before, the fermionic matter fields $\psi_\alpha$ live on the vertices of a lattice, while for non-Abelian gauge fields it is convenient to represent link variables by \textit{rishon} fermionic fields $\phi^\alpha$ and $\phi^\dagger$ living on the links to the left and right of a given site, $U_{x,x+1} = \phi^\dagger \phi^\dagger_{x+1}$ [11, 44] (see Fig. 3(a)). The U(2) gauge symmetry is split into a U(1) part, with generator $G_x = \psi^\dagger \psi_x - (\phi^\dagger_{x+1} \phi^\dagger_x - \phi^\dagger_{x-1} \phi^\dagger_{x-1})/2 + (\phi^\dagger_{x+1} \phi^\dagger_{x-1})/2 - 1$, and a SU(2) part, with generators $G^a = \psi^\dagger \sigma^a \psi_x + r^\dagger \sigma^a \phi^\dagger _x + r^\dagger \sigma^a \phi^\dagger _{x-1} - r^\dagger \phi^\dagger _x \sigma^a \phi^\dagger _{x-1}$, $a = 1, 2, 3$.

The $G^a$ commute with all $G_x$ and satisfy $[G^a_x, G^b_y] = 2i \delta_{xy} \epsilon_{abc} G^c_x$, where $\epsilon_{abc}$ is the Levi–Civita tensor and $\sigma^a$ are Pauli matrices.

The basic system dynamics described by $H_J$ is illustrated in Fig. 3(a); it corresponds to a simultaneous
hopping of two particles, namely $\psi_x$ to $r_x$ and simultaneously $l_{x+1}$ to $\psi_{x+1}$. The color of both particles is preserved during the process ($[H_0, G^x] = 0$). In a typical microscopic implementation, one may obtain additional, undesired color-changing terms of the form $H^{(1)}_1 = \lambda \sum_x (\psi^2_{x+1} \psi^2_x + r^2_{x+1} r^2_x + h.c.)$, as illustrated in Fig. 3(b). These do not commute with all generators, and therefore violate gauge invariance. To estimate the effect of terms such as this one, we analyzed the exact time evolution for two building blocks of the $U(2)$ model. We included various realistic errors similar to $H^{(1)}_1$ that are specific for the cold-atom implementation described in [31], comprising a large class of generic errors. As Fig. 3(c) shows, without protection the mean value of the sum of all generators, $\bar{g}^2 = \sum_x (\langle G^2_x + \sum_n (G^2_n) \rangle / N_s$, quickly acquires large values, indicating the loss of gauge-invariance (red line). However, under the noise protection generated by Eq. (1), gauge invariance may be retained on the time scale of several tunneling events (green dashed lines). This example demonstrates that the proposed protection mechanism works also for more complicated non-Abelian models including several non-commuting generators.

**Optical-lattice implementation.** In ultracold-atom implementations where the color index is represented by different internal atomic states, the standard strategy to suppress gauge-variant terms via quadratic energy penalties $U(G^x)^2$ amounts to engineering numerous local and non-local interactions with fine-tuned coefficients. From this regard, our dissipative approach is advantageous, since the preservation of gauge invariance requires driving the system with terms that are only linear in the generators. In the ultracold-atoms setting, the on-site single-particle noise terms $\zeta^x(t) G^x$ can be realized by coupling internal atomic states to laser fields with suitable amplitude or phase noise, where noisy AC-Stark shifts and Raman processes allow to impose the constraints on $G^x$ and $G^y$, as well as $G^x_0$ and $G^y_0$ (see [31]). Together with single-site addressing [12, 13], it is possible to engineer an independent noise source for each generator, as required by Eq. (1). Even more, if the dominant gauge-variant perturbations couple only nearest neighbors, one can simplify the experimental setup by using a noise pattern that is repeated periodically. In this way, one can enforce local gauge invariance by using global addressing together with a superlattice structure [31].

The last ingredient to quantum simulate the SU(2) LGT is then a natural realization of $H_0$ that does not interfere with the dissipative protection and thus does not lead to undesired heating of the system by the noise. In [31], we illustrate how models with $U(N)$ interactions (in particular focusing on the conceptually simpler $U(2)$ case) can be engineered in spinor gases, where spin-changing collisions combined with state-dependent optical potentials provide a natural realization of the two-body interaction terms constituting $H_J$. Ideas along these lines for Abelian theories have also been discussed in Ref. [12].

The scheme outlined above could also be combined with energetic protection in cases where, e.g., the interactions only protect an Abelian symmetry, while the more challenging non-Abelian contributions are imposed via noise. This would facilitate the realization of previous proposals [10], extending their regime of applicability and providing additional means to improve the accuracy of gauge invariance in microscopic realizations.

**Imperfections.** In an experimental realization of the above scenario, the noise may not couple perfectly to the generators, but to slightly different operators $\tilde{G}_x = G_x + \epsilon f_x$, with $\epsilon \ll 1$. Since the resulting dissipative terms in the master equation (2) read $\kappa (2G_x \rho G_x \rho - G^2_x \rho - G^2_x \rho)$, the effects of such imperfect couplings scale, in general, linearly with $\epsilon$. However, the most common case will simply be a perturbed relative weight of the different terms in the generators, such as $f_x = \psi^2_x \psi^2_x$ for the $U(1)$ model considered above. In this case $[G_x, f_x] = 0$ and the effects of imperfect coupling scale as $\epsilon^2 \kappa$, as long as the system remains in the gauge-invariant subspace. Requiring that $\epsilon$ be small compared to the scale $J$ imposes $\epsilon \ll \sqrt{J / \kappa}$ (instead of $\epsilon \ll J / \kappa$ as one would expect naively). As shown by the numerical calculations of the master equation for the $U(1)$ model, the electric field evolves consistently with the quadratic scaling with $\epsilon$ (Fig. 4).

**Conclusions and Outlook.** We have shown how classical noise can serve as a resource to engineer constrained Hamiltonian dynamics in quantum simulators, and in particular how Abelian and non-Abelian gauge invariance can be protected in atomic lattice implementations. The dissipative scheme has advantages with respect to the more conventional energy punishment, as coupling to generators is linear, local, and introduced by a physical resource which is independent of the engineered Hamiltonian dynamics. The mechanism is universal, as it can be extended to any symmetry and dimensionality, and can be applied to different microscopic systems beyond cold atom gases, such as superconducting qubits and trapped ions [28, 29].

Supplemental Material to

Constrained dynamics via the Zeno effect in quantum simulation: Implementing non-Abelian lattice gauge theories with cold atoms

In this supplemental material, we show how classical noise leads to an effective evolution within a gauge-invariant subspace, suppressing gauge-variant errors. We also present a possible implementation of a non-Abelian lattice gauge theory that does not interfere with the engineered noise, relying on spin-changing scattering processes between two fermionic species in a spin-dependent optical lattice.

I. NOISE PROTECTION IN THE MASTER EQUATION FORMULATION

Here, we present the derivation of the effective master equation described by Eq. (3) of the main text. This provides an intuitive explanation of the non-Hermitian part of the effective Hamiltonian $H_{\text{eff}}$ in terms of a loss of population to the gauge-variant subspace.

A. Elimination of classical noise variables

We start from the Hamiltonian coupled to classical Gaussian white noise variables, Eq. (1) in the main text. The associated time evolution of the system density matrix is governed by the master equation, [1, 2]

$$\dot{\rho} = \mathcal{L}_0 \rho + \sum_{x,a} \xi_{x}^{a}(t) \mathcal{L}_{x}^{a} \rho,$$

$$\mathcal{L}_{0} \rho = -i[H, \rho], \quad \mathcal{L}_{x}^{a} \rho = -i\sqrt{2\kappa}[G_{x}^{a}, \rho].$$

Here, the total Hamiltonian is given as $H = H_0 + H_1$ with $H_0(H_1)$ the gauge invariant (gauge variant) pieces as in the main text. We interpret Eq. (S1) as a Stratonovich stochastic differential equation (SDE) $d\rho = \mathcal{L}_0 dt + \sum_{x,a} dW_{x}^{a} \mathcal{L}_{x}^{a} \rho$, where the $dW_{x}^{a}$ are independent Wiener increments [3]. This equation can be converted to an Ito SDE, which then allows us to average over the classical noise in a straightforward manner. As a result of this procedure, we obtain the following master equation for the noise-averaged density operator $\langle \rho \rangle$:

$$\langle \dot{\rho} \rangle = \mathcal{L}_0 \langle \rho \rangle + \frac{1}{2} \sum_{x,a} \mathcal{L}_{x}^{a} \mathcal{L}_{x}^{a} \langle \rho \rangle = -i[H, \langle \rho \rangle] + \kappa \sum_{x,a} (2G_{x}^{a} \langle \rho \rangle G_{x}^{a} - (G_{x}^{a})^{2} \langle \rho \rangle - \langle \rho \rangle (G_{x}^{a})^{2}).$$

(S3)

This is the result quoted in Eq. (2) of the main text, where we dropped the angular brackets for notational simplicity. Note that $\kappa$ can be much larger than the system energy scales entering $H_0, H_1$, respectively.

B. Projected Master Equation

We are interested in the detrimental situation where the scales in the total Hamiltonian $H = H_0 + H_1$, $H_0 \sim J$ and $H_1 \sim \lambda$, are of the same order, $J \approx \lambda$. On the other hand, the scale of the dissipative terms $\sim \kappa$ is assumed to obey $\kappa \gg \lambda$. In this regime, we can adiabatically eliminate the fast dynamics generated by the dissipative part of the evolution. Note that, crucially, the desired gauge-invariant Hamiltonian $H_0$ and the gauge-variant perturbation $H_1$ can involve comparable energy scales; the protection mechanism builds only on the noise level $\kappa$ being the largest scale in the problem. We introduce projectors $P$ and $Q = 1 - P$, where $P$ projects on the gauge invariant subspace $H_{P}$ of the Hilbert space, as in the main text. The operators read in these projections (we replace $\langle \rho \rangle \rightarrow \rho$ for notational simplicity),

$$\rho = \begin{pmatrix} \rho_{PP} & \rho_{PQ} \\ \rho_{QP} & \rho_{QQ} \end{pmatrix}, \quad H = \begin{pmatrix} H_{PP} & H_{PQ} \\ H_{QP} & H_{QQ} \end{pmatrix}, \quad G_{x}^{a} = (G_{x}^{a})^\dagger = \begin{pmatrix} 0 & 0 \\ 0 & G_{x}^{a} \end{pmatrix},$$

(S4)

where $\rho_{PP} = P \rho P$ etc. In particular, the Hermitian gauge generators act nontrivially only in the gauge-variant subspace. Adiabatically eliminating the coherences $\rho_{PP}$, we find the evolution in the physical subspace

$$\partial_{t} \rho_{PP} = -i[H_{PP}, \rho_{PP}] - H_{PQ}(\kappa \sum_{x,a} G_{x}^{a} G_{x}^{a})\frac{1}{Q}QH_{PP}P - \rho_{PP} H_{PQ}(\kappa \sum_{x,a} G_{x}^{a} G_{x}^{a})^{-1}QQH_{PP},$$

(S5)
which is the master equation for the effective Hamiltonian given in Eq. (3) of the main text (note for comparison with the text $H_{PQ} = PHQ = PH_1Q$ and analogous for $H_{QF}$; $H_0$ has vanishing matrix elements in the above projection). This equation does not have Lindblad form and therefore may seem to violate the conservation of probability. To see that this is in fact not the case, we have to study $\partial_t \rho_{P} = \partial_t \rho_{PP} + \partial_t \rho_{PQ}$, where $\partial_t \rho_{Q} = -i(H_{QF}\rho_{PQ} - \rho_{QF}H_{PQ}) + \kappa \sum_{x,a}[2G_x^0\rho_{Q}G_x^2 - \{G_x^0G_x^2,\rho_{Q}\}]$ in the above decomposition. There is an explicit cancellation between the terms, which separately do not preserve the norm. The net effect of the second and third terms in (S5), therefore, is a loss of probability to be in the gauge-invariant subspace.

II. SPIN-CHANGING COLLISIONS AND LOCAL NOISE OPERATIONS FOR OPTICAL LATTICE IMPLEMENTATIONS

In this section, we explain how to implement the two crucial ingredients for a quantum simulation of a U(2) lattice gauge theory, (i) a way to generate the dynamics $H_0$ that is robust against the added noise, and (ii) a possibility to couple the noise to the symmetry generators.

A. Correlated hopping from spin-changing collisions

In the rishton representation as used in Eq. (5) of the main text, the correlated hopping term $H_J$ is a product of four field operators. In a gas of ultracold atoms, such products appear naturally in the form of atom–atom scattering processes, providing us with an elegant possibility of realizing $H_0$ via spin-changing collisions.

1. Scattering Hamiltonian

In second quantization, two-body collisions between atoms are described by the Hamiltonian

$$H_{\text{int}} = \frac{1}{2} \sum_{\alpha,\beta,\gamma,\delta} \int d^3r d^3r' \hat{O}_\gamma^\dagger(r) \hat{O}_\gamma^\dagger(r') \tilde{V}_{\alpha,\beta,\gamma,\delta}(r, r') \hat{O}_\beta(r') \hat{O}_\alpha(r).$$

Here, the $\hat{O}_\alpha$ denote (fermionic) field operators and the greek indices $\alpha \equiv \{s_\alpha, m_\alpha\}$ summarize internal states $m_\alpha$ as well as a species index $s_\alpha$. At low temperatures, we can express the interaction matrix elements as a contact interaction $\tilde{V}_{\alpha,\beta,\gamma,\delta}(r, r') = V_{\alpha,\beta,\gamma,\delta}(r - r')$, which gives

$$H_{\text{int}} = \frac{1}{2} \sum_{\alpha,\beta,\gamma,\delta} \int d^3r \hat{O}_\gamma^\dagger(r) \hat{O}_\gamma^\dagger(r) V_{\alpha,\beta,\gamma,\delta}(r) \hat{O}_\beta(r) \hat{O}_\alpha(r).$$

The interaction obeys the Pauli exclusion principle, it conserves angular momentum, $m_\delta = m_\alpha + m_\beta - m_\gamma$, and it cannot change the species, $s_\alpha = s_\delta$ and $s_\beta = s_\gamma$. Moreover, for fermions, the interaction matrix elements are anti-symmetric $V_{\beta,\alpha,\gamma,\delta} = V_{\alpha,\beta,\gamma,\delta} = -V_{\alpha,\beta,\gamma,\delta}$ etc.

The $V_{m_1, m_2}$ (where we suppressed the species index) are not all independent, but can be expressed by just a few parameters $V_F$, where $F$ denotes the total spin of the two-particle eigenstates, with associated magnetic quantum number $M_F$. For atoms with individual spins $F_{1,2}$, one has [4]

$$V_{m_1, m_2} = \sum_F \langle F_1, F_2 | F, M_F \rangle \langle F, M_F | F_1, F_2, m_1, m_2 \rangle V_F,$$

where the $\langle F_1, m_1, F_2, m_2 | F, M_F \rangle$ are Clebsch–Gordan coefficients. For homonuclear scattering, symmetry requirements restrict the total spin to $F = 0, 2, \ldots, F_1 + F_2 - 2, F_1 + F_2$, whereas for heteronuclear scattering one has $F = 0, 1, \ldots, F_1 + F_2 - 1, F_1 + F_2$.

2. Expansion in Wannier functions of the optical lattice

The main idea to pass from the scattering Hamiltonian (S7) to $H_J$ is to associate a spatial dependence to certain scattering processes. This can be achieved via a spin-dependent optical lattice. Since in that case different spin
states occupy different lattice wells, certain spin-changing collisions are necessarily accompanied by hopping processes (similar to the Abelian implementation proposed in [5]). As a concrete example, we consider two fermionic species, denoted by \( s = \Psi, \Phi \), each with four internal degrees of freedom \( m = \frac{-3}{2}, -\frac{1}{2}, \frac{1}{2}, \frac{3}{2} \) (for simplicity, we assume that these are the sublevels of a \( F_{1,2} = 3/2 \) hyperfine manifold). We denote the associated field operators by \( \hat{O}_{\Phi, m_\sigma}(r) \equiv \Phi_{m_\sigma}(r) \) and \( \hat{O}_{\Psi, m_\sigma}(r) \equiv \Psi_{m_\sigma}(r) \). The atoms are loaded in the species-dependent optical lattice sketched in Fig. S.1(a). Every second well will represent a site \( x \), and can only be populated by a single species in an alternating fashion; e.g., \( \Phi \) for \( x \) even and \( \Psi \) for \( x \) odd. Further, the sites trap only two internal states, say, \( m = -1/2, 3/2 \). The links \( \{x, x+1\} \) are represented by the remaining wells. They can be populated by both species but only by the remaining two internal states \( m = -3/2, 1/2 \). Spin-dependent optical lattices (although in simpler configurations) are routinely produced in experiment [6–9]. To illustrate the main idea how to obtain \( H_f \) from spin-changing collisions, we consider in the following first an idealized case. Afterwards, we show that in more realistic situations various imperfections appear. These, however, can be sufficiently suppressed by the engineered noise.

In a sufficiently deep optical lattice, we can as usual expand the field operators in terms of Wannier functions,

\[
\hat{O}_\alpha(r) = \sum_{i \in A_\alpha} \hat{O}_{i, \alpha} w_i(r), \tag{S9}
\]

where \( \hat{O}_{i, \alpha} \) annihilates a fermion in state \( \alpha \) at well \( i \), with associated Wannier function \( w_i(r) \). The sum runs over the set of wells \( A_\alpha \) that are accessible to atoms in state \( \alpha \). In the following, odd wells become associated to sites \( x \) of the quantum link model by \( (i+1)/2 = x \), and even lattice wells denote the corresponding links \( \{x, x+1\} \). To achieve the desired correlated hoppings, we choose a spin-dependent lattice where \( A_\alpha = \{x| x \text{ even}\} \) if \( s_\alpha = \Phi \) and \( m_\alpha = -1/2, 3/2 \), \( A_\alpha = \{x| x \text{ odd}\} \) if \( s_\alpha = \Psi \) and \( m_\alpha = -1/2, 3/2 \), and \( A_\alpha = \{\{x, x+1\}| m_\alpha = -3/2, 1/2 \} \). For simplicity, we assume that \( w_i(r) \) depends only on whether the well denotes a link or a site, but not on species or spin state.

In this Wannier expansion (using, without loss of generality, real Wannier functions), the collision Hamiltonian becomes

\[
H_{\text{int}} = \frac{1}{2} \sum_{\alpha, \beta, \gamma, \delta} \sum_{i \in A_\alpha, j \in A_\beta, k \in A_\gamma, l \in A_\delta} \sum_{r} V_{\alpha, \beta, \gamma, \delta} \int d^3 r w_i(r) w_j(r) w_k(r) w_l(r) \hat{O}_{i, \alpha}^\dagger \hat{O}_{j, \beta} \hat{O}_{k, \gamma}^\dagger \hat{O}_{l, \delta}. \tag{S10}
\]

Already for moderately deep lattices, due to the exponential decay of Wannier functions, we can neglect terms involving wells that are not nearest neighbors or constituted by the triples \( x-1, \{x-1, x\}, x \) (we assume that the wells associated to the links \( \{x, x+1\} \) are much deeper than wells associated to the sites \( x \), so that the overlap of triples \( \{x-1, x\}, \{x, x+1\} \) can be neglected).

Due to the spin-dependence of the optical lattice, collision terms including the three wells \( x-1, \{x-1, x\}, x \) are necessarily spin-changing (see Fig. S.1(a)). If, for the moment, we assume that all corresponding scattering rates are equal, these collision terms yield the Hamiltonian

\[
H'_{\text{int}}/J = \sum_{x \text{ even}} \sum_{\sigma, \sigma'} \left( \Phi^{\sigma} \Phi^{\sigma'} \Psi^{\sigma'} \Psi^{\sigma} + \text{h.c.} \right) + \sum_{x \text{ odd}} \Phi \leftrightarrow \Psi \tag{S11}
\]

\[
+ \sum_{x \text{ even}} \left( \Phi^{\frac{1}{2}} \phi^{\frac{1}{2}} \right) \left( \Phi^{\frac{1}{2}} \phi^{\frac{1}{2}} \right) + \sum_{x \text{ odd}} \left( \Phi^{\frac{1}{2}} \phi^{\frac{1}{2}} \right) \left( \Phi^{\frac{1}{2}} \phi^{\frac{1}{2}} \right) + \Phi \leftrightarrow \Psi.
\]
The associated process is explained in Fig. S2.

Besides the desired terms, the interaction Hamiltonian (S10) leads to a series of undesired terms, which can reach energy scales comparable to the desired ones. For example, the second line of Eq. (S11) contains color-changing processes that are gauge-variant perturbations. Following the mapping (S12), these can be written as

$$H_J = J \sum_c \sum_{x} \left( \psi^c_{x-1} \phi^{c \dagger}_{x-1} \right) + \text{h.c.}$$

(S13a)

$$H_J = J \sum_{c,d=1,2} \left( \phi^{c \dagger}_{x-1} \phi^d_{x-1} \right) + \text{h.c.}$$

(S13b)

The associated process is explained in Fig. S2.

Besides the desired terms, the interaction Hamiltonian (S10) leads to a series of undesired terms, which can reach energy scales comparable to the desired ones. For example, the second line of Eq. (S11) contains color-changing processes that are gauge-variant perturbations. Following the mapping (S12), these can be written as

$$H_J^{(1)} = \psi^a_{x} \phi^a_{x} \phi^b_{x} \phi^b_{x} + \sum_{c=1,2} \left( \psi^c_{x} \phi^c_{x} \phi^c_{x} \phi^c_{x} + \phi^c_{x} \phi^c_{x} \phi^c_{x} \phi^c_{x} \right) + \text{h.c.}$$

(S14)

Another perturbation appears when we relax the idealized assumptions leading to Eq. (S11). Without unrealistic fine tuning, the scattering elements $J^{a,b}_{\alpha,\beta}$ will not be all equal because of differences in the Clebsch–Gordan coefficients for different spin states. One can capture this effect by including the error term

$$H_J^{(2)} = \sum_{c,d=1,2} \Delta J_{cd} \psi^c_{x-1} \phi^c_{x-1} \phi^d_{x} \phi^d_{x} + \text{h.c.}$$

(S15)

In the formulation of this error term, we exploited symmetries of the microscopic scattering interaction to reduce the number of independent scattering matrix elements to just two, namely $J_{12} = J_{21}$ and $J_{11} = J_{22}$. These determine the
strength of the desired correlated hopping, \( J \equiv (J_{11} + J_{12})/2 \), and of the error term \( \Delta J_{cd} \equiv J_{cd} - J \). Other error terms appear due to scattering processes that do not involve all three wells of a building block, such as on-site density–density interactions. All of these terms are listed in Table I, along with exemplary values for their strength, which are used in the numerics (see below). Besides the error terms appearing due to scattering processes, as listed in Table I, gauge variance could be broken by single-particle tunneling. In the above geometry, however, the Wannier functions of the rishon wells are strongly localized, so that rishon tunneling can be neglected. Additionally, the sites are occupied by two species in an alternating pattern, precluding nearest-neighbor tunneling between sites \( x \) and \( x + 1 \). Therefore, single-particle tunneling is strongly suppressed compared to the desired dynamics and other error sources.

3. Numerical simulation of a small system

To illustrate the dissipative protection scheme for the case of the U(2) quantum link model, we have performed exact numerical simulations of a small system consisting of two building blocks with periodic boundary conditions. The results are displayed in Fig. 3(b) of the main text and were obtained by integrating the master equation (2) of the main text, with the Hamiltonian containing all terms listed in Table I. The gauge-invariant initial state was chosen to be

\[
|\psi_0\rangle = \frac{1}{\sqrt{2}} \left( (\bar{\psi}_1^{\dagger} \psi_1^{\dagger} - \bar{\psi}_1 \psi_1) \frac{1}{\sqrt{2}} \left( \bar{\psi}_2^{\dagger} \psi_2^{\dagger} - \bar{\psi}_2 \psi_2 \right) \right) |0\rangle
\]

and has exactly one rishon per link. If the gauge-variant terms are suppressed by dissipation, then the single occupation of links is approximately conserved by the dynamics, which has the advantage of making rishon density–density interactions irrelevant (allowing to neglect the barred-out terms in Table I). The choice of one rishon per link corresponds to choosing a particular representation of U(2), although other possibilities (like, e.g., two rishons per link) are also allowed. In general, a one-rishon-per-link representation is possible for all U(N) QLMs (but not in the SU(N) case) [10, 11]. As can be seen from Fig. 3(b) of the main text, gauge invariance is violated for vanishing dissipation (\( \kappa = 0 \)), and restored for increasing \( \kappa/J \), thus confirming the versatility of the dissipative protection scheme also for the non-Abelian U(2) quantum link model.

B. Realization of noise constraints

Now, we briefly describe how the noise sources required by Eq. (1) of the main text can be added to the optical-lattice setup outlined in the previous section. Before proceeding to the specific example of the U(2) quantum link model, we stress that the Hermitian nature of the generators leads to the following additional freedom in the implementation: The Lindblad terms appearing in Eq. (2) of the main text, \( 2\Gamma_\rho G - G^\dagger \rho G - \rho G^2 \equiv \mathcal{D} (G) \rho \) are invariant under a constant shift, i.e., \( \mathcal{D} (G + \text{const.} \times 1) \rho = \mathcal{D} (G) \rho \). This means that constants appearing in the generators can be ignored, since their presence is not important for the dissipative dynamics that we are interested in. In the following, we will exploit this fact several times to show how protection by classical noise can be achieved for the specific case of the U(2) model. To do so, we consider color-changing and color-preserving generators separately.

1. Color-preserving generators \( G_x \) and \( G_x^3 \)

The generators \( G_x \) and \( G_x^3 \) are linear functions of fermion and rishon number operators and hence preserve the color degree of freedom. The corresponding terms in the noise Hamiltonian appearing in Eq. (1) of the main text can be written as

\[
H_n^x = \sqrt{2\kappa} \sum_x \xi_x^3(t) G_x^3 + \sqrt{2\kappa} \sum_x \xi_x(t) G_x^4
\]

\[
= \sqrt{2\kappa} \sum_x \xi_x^3(t) \left[ N_x^1 - N_x^2 \right] + \sqrt{2\kappa} \sum_x \xi_x(t) \left[ \psi_x^\dagger \psi_x^0 - \frac{1}{2} (n_x^{1\dagger} n_x^{a\dagger} - n_x^{1\dagger} n_x^{a\dagger} - n_x^{1\dagger} n_x^{a\dagger}) + \frac{1}{2} (l_x^{1\dagger} l_x^{a\dagger} - l_x^{1\dagger} l_x^{a\dagger}) \right] .
\]

Here, \( N_x^c = n_x^c + n_x^{a\dagger} + n_x^{a\dagger} \) is the total number of particles with color \( c = 1, 2 \) on building block \( x \). In addition, \( G_x^4 \) denotes \( G_x \) without the constant contribution, which we dropped due to its irrelevance as explained above. Noise terms as in the above Hamiltonian can be realized by noisy AC-Stark shifts introduced by off-resonant lasers with intensity noise. Note that the generators involve atoms in several wells, which leads to a spatially correlated noise pattern. This can be achieved easily by using the same noise signal to control the AC-Stark shift on the involved wells, or even by using the same laser to address those wells.
The second column gives the processes in terms of the rishon representation of the U(2) model. Here, $\Phi = \frac{1}{2}, \frac{1}{2}$ such that the density-density interactions which are barred out do not contribute (see text).

\[
J = (J_{11} + J_{12})/2
\]

\]

TABLE I. Interaction strengths for the scattering processes contained in $H_{\text{int}}$. For reference, the first row contains the desired correlated hopping $H_J$, which is generated by the physical processes in the second and third row. The difference between $J_{11}$ and $J_{12}$ leads to the gauge-variant perturbation given in Eq. (S15). All other scattering processes of $H_{\text{int}}$ constitute additional error terms. The second column gives the processes in terms of the rishon representation of the $U(2)$ model. Here, we defined $\bar{c} = (c \mod 2 + 1)$, as well as $n_{\bar{c},x} = \psi_{\bar{c}}^{x\dagger} \psi_{\bar{c}}^{x}$, $n_{\bar{c},x} = r_{\bar{c},x}^{+} r_{\bar{c},x}$, and $n_{\bar{c},x} = \bar{r}_{\bar{c},x}^{+} \bar{r}_{\bar{c},x}$. The second (third) column contains the involved species (internal levels). The fourth column gives the Wannier overlaps entering the interaction strengths, which read $I_0 = \int d^3r w_{2,x}^{c}(r)w_{2,x}^{c\dagger}(r)$, $I_1 = \int d^3r w_{2,x}^{c}(r)w_{2,x}^{c\dagger}(r)$, $I_2 = \int d^3r w_{2,x}^{c}(r)$, and $I_3 = \int d^3r w_{2,x}^{c}(r)$. Due to the different extension of Wannier functions (wells associated to links are deeper), their strength will increase from $I_0$ to $I_3$, with precise values depending on the implementation. In our numerical calculations, we choose the relative weights $1:5:25:30$. Furthermore, we use the scattering lengths (with $a_0$ the Bohr radius) $V_{22,22}^{\Phi,\Phi} = -220a_0$, $V_{22,22}^{\Phi,\Phi} = 280a_0$, $V_{22,22}^{\Phi,\Phi} = -250a_0$, $V_{22,22}^{\Phi,\Phi} = 300a_0$, as well as $V_{22,22}^{\Phi,\Phi} = 360a_0$, $V_{22,22}^{\Phi,\Phi} = 4a_0$, and $V_{22,22}^{\Phi,\Phi} = 5a_0$. The actual values of these parameters will depend on details of the experimental realization. They are chosen here to give a sensible order-of-magnitude estimate. We adjusted them only in a rough way in order to keep the most detrimental errors small, but assumed no fine tuning. From these scattering lengths, together with the Wannier overlaps, one obtains the relative interaction strengths as given in the last column. In cases where there are two entries, the first one is for even and the second for odd sites (corresponding to intra-species scattering of $\Phi$ and $\Psi$, respectively). Intra-species scattering processes have a factor of 2 with respect to inter-species collisions due the contribution from exchange interactions. Finally, in our numerical calculations, we assume a representation where there is only one fermionic rishon per link, such that the density-density interactions which are barred out do not contribute (see text).
are not trapped on the respective wells (boxes denote sites, and circles denote links, see Fig. S1).

\[ I \]

For brevity, we introduce the “intensity” \( I(t) \equiv \Omega^2(t)/\Delta \equiv I_0 + \delta I(t) \), with mean \( I_0 \) and fluctuations of magnitude \( \delta I(t) \). For small fluctuations \( \delta I/I_0 \ll 1 \) and \( \delta \phi \ll 1 \) as illustrated in Fig. S3(b), we can expand \( I(t)e^{i\delta \phi} \approx I_0 + \delta I(t) + \)
\[iI_0 \delta \phi(t) + \ldots, \text{ such that Eq. (S22) becomes}\]

\[
H_{\text{Raman}} \approx I_0 \left[ G_x^1 + N_x^1 + N_x^2 \right] + \left[ (\delta I(t) + iI_0 \delta \phi(t)) (\psi^2_x \psi^2_x + i\gamma^2_x r^1_x + r^2_x r^1_x) + \text{h.c.} \right] + \delta I(t) \left[ N_x^1 + N_x^2 \right].
\]  

(S23)

The first bracket only gives rise to trivial dynamics, as long as we are in the gauge-invariant subspace (where \( G_x^1 \) has eigenvalue 0) and the number of particles \( N_x^1 + N_x^2 \) per building block is preserved, as it is the case for a system evolving according to \( H'_{\text{int}} \) (see Table I). The second bracket is the desired noise Hamiltonian displayed in Eq. (S20), with \( \xi_1 + i\xi_2 \propto \delta I + iI_0 \delta \phi \), such that intensity and phase fluctuations coupling to \( G_x^1 \) and \( G_x^2 \), respectively. In addition, the third bracket is an undesired random stark shift, which is again irrelevant due to the conservation of \( N_x^1 + N_x^2 \).

In order to realize the noise protection scheme outlined in the main text, the two signals \( \delta \phi(t) \) and \( \delta I(t) \) need to represent white noise sources. Since white noise is an idealization, we briefly describe how to choose the noise processes if we assume that they behave as Ornstein–Uhlenbeck processes [2]

\[
d\delta I = -i\gamma_I \delta I dt + \sqrt{D_I} dW_I,
\]

(S24)

\[
d\delta \phi = -i\gamma_\phi \delta \phi dt + \sqrt{D_\phi} dW_\phi,
\]

(S25)

with relaxation rates \( \gamma_I, \phi \), diffusion constants \( D_{I,\phi} \), and uncorrelated Wiener increments \( dW_{I,\phi} \) [3]. The white-noise limit is reached when the correlation times \( 1/\gamma_{I,\phi} \) are much shorter than any other time-scale of the problem, in particular \( 1/\gamma_I \ll 1/\lambda \), with \( \lambda \) the scale of the gauge-variant error terms. The diffusion constants can then be adjusted to meet the conditions for the small-noise expansion carried out above, i.e., \( \ll I_0^2 \) and \( \ll 1 \), such that the second bracket in Eq. (S23) realizes the desired noise Hamiltonian Eq. (S20).

Averaging over the noise in Eq. (S23) and taking the white-noise limit [3] yields, in accordance with our earlier developments in Sec. I.A, a master equation with two Lindblad terms:

\[
\langle \dot{\rho} \rangle \approx \kappa_1 \mathcal{D}[G_x^1 + N_x^1 + N_x^2] \langle \rho \rangle + \kappa_2 \mathcal{D}[G_x^2] \langle \rho \rangle.
\]

(S26)

where \( \kappa_1 = D_I/2\gamma_I^2 \) and \( \kappa_2 = D_\phi/2\gamma_\phi^2 \). Since \( N_x = N_x^1 + N_x^2 \) is a constant of motion under \( H'_{\text{int}} \), we can finally replace \( \mathcal{D}[G_x^1 + N_x] \rightarrow \mathcal{D}[G_x^1] \), as discussed above. The coupling scheme presented here thus gives rise to the desired dissipative coupling to the generators \( G_x^1,2 \). Together with the noisy AC-Stark shifts coupling to \( G_x^1 \) and \( G_x^2 \) outlined in the previous subsection one is thus able to realize the intended dissipative protection of gauge-invariant dynamics.

Finally, we point out an alternative for the realization of \( H'_{\text{noise}} \), which is depicted in Fig. S3(c,d): Instead of using a single Raman transition with amplitude and phase noise, one could realize Eq. (S20) by using a separate Raman transition for \( G_x^1 \) and \( G_x^2 \). This scheme works analogously to the one described above, but requires only intensity noise.

### 3. Multiple building blocks

To generate the above noise on all building blocks \( x \), one has to shine laser beams onto the cloud that are tuned to the appropriate transitions and that address only a few optical-lattice wells (the wells constituting a given building block) in a correlated manner. Typically, the perturbations contained in \( H_1 \) will only act locally, such as nearest-neighbor collision or tunneling processes. In such a case, one can allow correlations between the noise affecting nearest-nearest-neighbor building blocks \( x \) and \( x + 2 \). Since nearest-neighbor building blocks are occupied by different species, one can then use two global bundles of beams, one acting on species \( \Phi \) and one acting on \( \Psi \), thus generating noisy AC-Stark shifts and Raman transitions that are uncorrelated between neighboring building blocks. In cases where longer-range perturbations become relevant, one has to accordingly increase the periodicity after which the noise modulation is repeated. In the most general setting, independent noise sources can be achieved on each building block using single-site addressing techniques by shining lasers beams through holographic masks onto the sample [12, 13].

To achieve the correct coupling to the generators, one would desire a step-like profile of the laser beams, with support only on a given building block. However, realistic small deviations from this profile prove to be irrelevant. A finite overlap of a beam to the next building block may be disregarded, since here a different species resides to which the laser will not couple. Further, an imperfect weight of the noise sources within a given building block will typically induce errors only at second order in the imperfection strength (see Fig. 4 of the main text).
