(Received 30 October 2008; published 23 January 2009)

We present an analytic model to calculate the atomic scattering length near a Feshbach resonance from data on the molecular binding energy. Our approach considers finite-range square-well potentials and can be applied near broad, narrow, or even overlapping Feshbach resonances. We test our model on Cs2 Feshbach molecules. We measure the binding energy using magnetic-field modulation spectroscopy in a range where one broad and two narrow Feshbach resonances overlap. From the data we accurately determine the Cs atomic scattering length and the positions and widths of two particular resonances.

I. INTRODUCTION

In experiments on ultracold quantum gases, control of the atomic scattering length near Feshbach resonances has become a powerful tool to explore different interaction regimes [1]. Prominent examples include the implosion and explosion of Bose-Einstein condensates [2], the creation of ultracold molecules [3,4], strongly interacting Fermi gases [5,6], and the observation of three-body Efimov states [7]. Moreover, Feshbach resonances have been proposed as a very sensitive probe to the variation of fundamental constants [8].

For all such experiments precise knowledge of the atomic scattering potential length \(a\) is desirable. Usually a multichannel molecular potential model is employed to calculate the scattering length. This approach requires experimental input, as usually provided by photoassociative or Feshbach spectroscopic data [9–11]. It captures the global scattering behavior of the system and has a predictive power on Feshbach resonance positions with an uncertainty of typically a few hundred milligauss. In many experimental situations, however, precise knowledge of \(a\) is needed in the vicinity of specific Feshbach resonances at a level not reachable with this global approach.

We here consider the situation in which the scattering length \(a\) near a specific resonance is calculated using molecular binding energy data. Nowadays powerful experimental methods are available to measure the binding energy of Feshbach molecules with very high accuracy, such as radio-frequency and microwave spectroscopy [12–16]. For the relation between the binding energy \(E_b\) and \(a\), a simple analytic form can be given in the universal limit of very large positive values of \(a\). It is given by \(E_b = h^2/(2m_\text{a}a^2)\), with \(m_\text{a}\) being the reduced mass. In general, the relation between molecular binding energy and scattering length is more complex, depending also on short-range parameters of the molecular potentials. In principle, one may also use a multichannel calculation to precisely derive \(a\) from measurements of \(E_b\). When the specific scattering properties are needed near a particular Feshbach resonance, a much more simple model can be applied.

In this paper, we describe a versatile analytic model to directly convert molecular binding energy data into atomic scattering lengths near Feshbach resonances. Our approach considers square-well model potentials and can be applied to any broad or narrow Feshbach resonance, or even to the case of overlapping resonances. We demonstrate our model on Cs2 Feshbach molecules. Cesium is an excellent candidate to test scattering models because of its rich interaction properties [17,19]. From fitting the binding energy data, we show that the magnetic-field-dependent scattering length can be determined with high precision. We compare our results with the full multichannel numerical calculation of Ref. [17].

II. FESHBACH RESONANCE MODEL

We employ a two-channel square-well potential \(\hat{V}(R)\) to describe interacting atoms and weakly bound molecules near a Feshbach resonance. The well size is chosen to account for the long-range behavior of the molecular potential, which is dominated by the van der Waals (vdW) interaction \(\hat{V}(R) = -C_6/R^6\), where \(C_6\) is the vdW coefficient and \(R\) is the atomic separation. The associated vdW length scale and vdW energy scales are \(R_{\text{vdW}} = h^2/2m_\text{a}C_6\) and \(E_{\text{vdW}} = h^2/2m_\text{a}R_{\text{vdW}}^2\).

To fully capture the threshold behavior of atomic scattering with vdW interaction, the well size is chosen to be the mean scattering length \(\bar{a} = 4\pi\Gamma(1/4)^{-2}R_{\text{vdW}}\) [20], where \(\Gamma(x)\) is the gamma function. This choice yields the same binding energy of weakly bound molecules in the vdW potential: namely, \(E_b = h^2/2m_\text{a}(\bar{a} - \bar{a})^2\) for \(E_b \ll E_{\text{vdW}}\) [20].

In our model, scattering atoms are initially prepared in one spin configuration, called the “entrance channel” |\(e\)\>. A second “closed channel” |\(e\)\> supports a molecular bound state; see Fig. 1. The quantum state of an atomic pair with energy \(E\) is described as |\(\phi\rangle = \psi_e(R)|e\rangle + \psi_e(R)|e\rangle\), which satisfies Schrödinger’s equation

$$
\left(-\frac{\hbar^2}{2m_\text{a}} \nabla^2 + \hat{V}\right)|\psi\rangle = E|\psi\rangle,
$$

where, using a matrix representation, we write

$$
\hat{V} = \begin{bmatrix} -V_c & \hbar \Omega \\ \hbar \Omega & -V_e \end{bmatrix} \quad \text{(for } R < \bar{a}) = \begin{bmatrix} \infty & 0 \\ 0 & 0 \end{bmatrix} \quad \text{(for } R > \bar{a}).
$$

1050-2947/2009/79(1)/013622(6) 013622-1 ©2009 The American Physical Society
be derived from the continuity condition of the wave function. The entrance and closed-channel thresholds are set to be $E=0$ and $E=\infty$, respectively. See Fig. 1.

Here, for $R<\bar{a}$, we assume the attractive potential can support multiple molecular states—that is, $V_r,V_c=E_{\text{vdW}}$ and $h\Omega$ induces Feshbach coupling between the channels. For $R>\bar{a}$, entrance- and closed-channel thresholds are set to be $E=0$ and $E=\infty$, respectively. See Fig. 1.

A. Scattering state above threshold and scattering length

For $E=\hbar^2 k^2/2m_r>0$, the solution of Eq. (1) corresponds to an eigenstate lying above the entrance-channel threshold and is given by

$$|\psi\rangle = \frac{\sin(q_c R)}{R} (|+) + A \frac{\sin(q_c R)}{R} (-) \quad \text{(for } R<\bar{a})$$

$$\times \frac{\sin(kR + \eta)}{R} |e\rangle \quad \text{(for } R>\bar{a}),$$

where $A$ is a constant, $\hbar^2 q_c^2/2m_r = E + \frac{1}{2} (V_r + V_c) \pm \frac{1}{2} \sqrt{(V_r + V_c)^2 - 4V_r V_c}$, $|+\rangle = \cos(\theta_E) + \sin(\theta_E)$, and $|-\rangle = -\sin(\theta_E) + \cos(\theta_E)$. The scattering phase shift $\eta$ can be derived from the continuity condition of the wave function at $R=\bar{a}$, which gives

$$\sin(k\bar{a} + \eta) = q_c \frac{\cos^2 \theta + q_c \sin^2 \theta}{\tan(q_c \bar{a})} + q_c \frac{\sin \theta \cos \theta}{\tan(q_c \bar{a})},$$

Potential depths $V_r$ and $V_c$ can be chosen such that in the weak-coupling limit $\theta\to 0$, the scattering phase shift approaches the off-resonant value $\eta_{bg}$ and the closed-channel bound state is at $E_c$. These two conditions, given by

$$q_c = \frac{k}{\tan(q_c \bar{a})} = \frac{k}{\tan(k\bar{a} + \eta_{bg})},$$

allow us to eliminate $q_c$ and $q_c$ in Eq. (4). Assuming further that only one bare bound state is near the continuum $|E_c| \ll |V_c|$, and the Feshbach coupling is weak $|\theta| = \hbar \Omega/|V_c - E_c| \ll 1$, we get

$$\cot(k\bar{a} + \eta) = \cot(k\bar{a} + \eta_{bg}) - \frac{\Gamma/2}{k\bar{a}E_c},$$

where we have introduced the Feshbach coupling strength $\Gamma/2 = 2\theta^2 V_c$.

Scattering lengths can be derived from the threshold relation $a = \lim_{k\to 0} (k \cot \eta)^{-1}$. From Eq. (7), we get

$$\frac{1}{a - \bar{a}} = \frac{1}{a_{bg} - \bar{a}} + \frac{\Gamma/2}{a_{bg} E_c},$$

where $a_{bg} = \lim_{k\to \eta_{bg}} (k \cot \eta_{bg})^{-1}$ is the background scattering length.

The magnetic tunability of Feshbach resonances can be modeled by a linear Zeeman shift of the bare bound state as $E_b = \delta \mu(B-B_0)$, where $B$ is the magnetic field, $\delta \mu$ is the relative magnetic moment of the two channels, and $B_0$ is a magnetic field that tunes the bare state to the entrance-channel threshold. This magnetic-field dependence allows us to rewrite the scattering length in the standard resonance form $\alpha = a_{bg} \Delta/(B-B_0)$. Here the resonance width $\Delta$ and position $B_0$ are given by

$$\Delta = \delta \mu^{-1} \frac{\Gamma}{2},$$

$$B_0 = B_c - \beta \Delta,$$

where $\alpha = (a_{bg} - \bar{a})^2/a_{bg} \bar{a}$ and $\beta = a_{bg}/(a_{bg} - \bar{a})$ are dimensionless parameters.

B. Bound molecular state below threshold

We assume that a bound eigenstate $|\psi_m\rangle$ is located near and below the continuum with binding energy $E_b = \hbar^2 k^2_m/2m_r$. Solving Eq. (1), we obtain the wave function as

$$|\psi_m(R > \bar{a})\rangle = \exp(-k_m R)|e\rangle,$$

$$|\psi_m(R < \bar{a})\rangle = \frac{\sin(q_c R)}{\bar{a}} (|+) + A_m \frac{\sin(q_c R)}{\bar{a}} (-),$$

where $A_m$ is a constant and $\bar{q}_c = (q_c^2 - k^2 - k^2_m)^{1/2}$.

The binding energy $E_b$ can be determined from the boundary conditions at $R=\bar{a}$. Following the same calculation as that leading to Eq. (8), we find that for large background scattering length $|a_{bg}| \gg \bar{a}$, the wave number $k_m$ determining the binding energy $E_b = \hbar^2 k^2_m/2m_r$ satisfies

$$k_m = \frac{1}{a_{bg} - \bar{a}} + \frac{\Gamma/2}{\bar{a}(E_b + E_c)},$$

In the limit when the Feshbach coupling approaches zero, $\Gamma \to 0$, the eigenenergies reduce to $E_b = -E_c$ and

$$\sin[k^2_m = 0, \quad (6)$$

FIG. 1. (Color online) Two-channel square-well model of Feshbach resonances. Scattering states are initially prepared in the entrance channel $|e\rangle$; the closed channel $|c\rangle$ supports a bare bound state at energy $E_c$. Feshbach coupling is modeled by the mixing of the two channels, which is resonantly enhanced when the bound state is near the scattering state. The interaction range is set to be the mean scattering length of the atomic van der Waals potential; see text.
C. Multiple overlapping Feshbach resonances

The above-discussed model can be generalized to the case of multiple overlapping Feshbach resonances, which commonly occurs in cold collisions of alkali-metal atoms and chromium atoms.

Let us assume that \( N \) weakly bound states are supported by \( N \) independent closed channels. If the mixing between the closed channels and the entrance channel is weak and \( |a_{bg}| \gg \bar{a} \), we can extend Eq. (1) to model the scattering length and molecular energy. The results are

\[
\frac{1}{a - \bar{a}} = \frac{1}{a_{bg} - \bar{a}} + \frac{1}{\bar{a}} \sum_{i}^{N} \frac{\Gamma_i/2}{E_i},
\]

\[
k_m = \frac{1}{a_{bg} - \bar{a}} + \frac{1}{\bar{a}} \sum_{i}^{N} \frac{\Gamma_i/2}{E_{bg} + E_i},
\]

where \( E_i \) is the energy of the \( i \)th bare bound state and \( \Gamma_i \) is its Feshbach coupling strength to the entrance channel. The results presented here bear a similarity to those from classic Fano theory on the coupling of discrete states to a continuum [18].

Assuming that the bare states can be linearly tuned magnetically—namely, \( E_i = \delta \mu_i (B - B_{c,i}) \), where \( \delta \mu_i \) is the relative magnetic moment and \( B_{c,i} \) is the crossing field value of the \( i \)th bare bound state—we can express the scattering length as \( a/a_{bg} = 1 - P(B)/Q(B) \), where \( P(x) \) and \( Q(x) \) are polynomials of \((N-1)\)th and \( N \)th order, respectively. If we further assume all \( B_{c,i} \)'s are distinct and all \( \mu_i \)'s have the same sign, the scattering length expression can be factorized as

\[
a/a_{bg} = \prod_{i=1}^{N} \frac{B - B^*_{i}}{B - B_{c,i}}.
\]

Here we define \( B_{0,i} \) as the \( i \)th lowest pole of \( a/a_{bg} \) and \( B^*_{i} \) the \( i \)th lowest zero. This form is more convenient for experimental research since zeros and poles of the scattering length can be identified experimentally. Accordingly, the width of the \( i \)th Feshbach resonance can be defined as \( \Delta_i = B^*_{i} - B_{c,i} \).

FIG. 2. (Color online) Example of a loss resonance at 48.2 G. The losses are due to the coupling between atom pairs and \( d \)-wave molecules. The solid line is a Gaussian fit to the data. We find the resonant frequency to be \( \nu = 93.0(3) \) kHz and the width 5.5(6) kHz. The inset shows the typical magnetic-field sequence used to associate \( ^{133} \)Cs molecules with an oscillating magnetic field.

III. BINDING ENERGY MEASUREMENTS AND DETERMINATION OF THE SCATTERING LENGTH

A. Measurements of the binding energy

We measure the binding energies of ultracold \(^{133} \)Cs molecules in a magnetic-field range where a weakly bound \( s \)-wave molecular state overlaps with a \( d \)-wave and a \( g \)-wave state [19]. The latter two states are connected to the \( d \)-wave and \( g \)-wave Feshbach resonances located at about 48 G and 53.5 G, respectively [17]. Molecular spectroscopy is performed by using a weak oscillating magnetic field. This technique, previously applied to a \(^{85} \)Rb atomic sample [15] and to a \(^{85} \)Rb-\(^{87} \)Rb mixture [16], has the advantage of determining the binding energies of weakly bound molecules to within a few percent. The oscillating magnetic field stimulates a transition between an atom pair and a molecule for a modulation frequency resonant to \( E_j/h \) [15,21], where \( h \) is the Planck constant.

Our molecular spectroscopy is performed using ultracold Cs atoms in an optical trap. A detailed description of our experimental procedure can be found in Ref. [22]. After several precooling stages, the atoms are fully polarized in their absolute ground state \( |F=3, m_F=3\rangle \). We evaporatively cool the atoms in the optical trap at a magnetic field of 27 G [23], where the two-body scattering length is large enough (\( a = 450 a_0 \), with \( a_0 \) the Bohr radius) to provide fast thermalization. During the evaporation sequence, an extra magnetic-field gradient is applied to levitate the atoms against the gravity [24,25]. We typically obtain a nearly degenerate sample of 8000 Cs atoms at \( T = 100 \) nK. Typical values for the density and phase space density are \( 1.2 \times 10^{12} \text{ cm}^{-3} \) and 0.2, respectively.

We measure the molecular binding energy by magnetic-field modulation [15,21]. The inset of Fig. 2 shows the magnetic-field sequence. After ramping the magnetic field within 3 ms to a desired value in the range of interest, we add for typically 1 s a small sinusoidal magnetic field \( B(t) = A \sin(2 \pi \nu t) \), where the modulation amplitude \( A \) typically
ranges from 100 to 600 mG. We then ramp back the magnetic field to initial value and wait 100 ms, during which the associated molecules decay by inelastic collisions with the atoms. The magnetic field is then rapidly turned off to image the atoms with standard absorption imaging technique. If the modulation frequency \( \nu \) is close to the binding energy value, \( E_B = \hbar \nu \), the oscillating magnetic field couples atom pairs to molecules [21]. The atoms are converted into molecules, and the resulting association is detected as resonant loss in the atom number. A typical loss signal is shown in Fig. 2. The resonant frequency is determined to within a few percent by fitting the data with a Gaussian profile [26].

We determine the resonant loss frequency for different values of the magnetic field. Figure 3 shows the measured molecular spectrum (open circles) in the magnetic-field range between 25 G and 60 G. Here, three weakly bound molecular states—namely, s-, d-, and g-wave bound states—overlap near threshold [19,27]. We usually observe losses of Cs atoms up to 50%. The largest loss rate and hence conversion efficiency is observed when g-wave molecules are associated. This observation is consistent with the results of Ref. [21], which predict higher conversion efficiencies for larger relative magnetic moments \( \delta \mu \).

![FIG. 3.](image) Binding energy of cesium molecules near three Feshbach resonances as a function of the magnetic field. Zero energy corresponds to two Cs atoms in the absolute hyperfine ground-state sublevel \( |F=3, m_F=3\rangle \). The measurements are shown as open circles. The fit (solid line) is based on Eq. (13); see text. The inset shows an expanded view in the region of the two d- and g-wave resonances. The error bars refer to the statistical uncertainties.

![FIG. 4.](image) Scattering length of \( |F=3, m_F=3\rangle \) cesium atoms in the magnetic-field range where three Feshbach resonances overlap. The solid curve shows the result of this work, while the dashed curve represents the prediction from a previous multichannel calculation [17].

### B. Determination of the scattering length

We now convert the binding energy data into scattering length. For Cs atoms, the vdW energy is \( E_{\text{vdW,Cs}} = \hbar \times 2.7 \text{ MHz} \) and the mean scattering length \( \bar{a} = 95.7a_B \). We apply our model in the regime \( E_B < E_{\text{vdW,Cs}} \) by fitting the binding energy data with Eq. (13) for overlapping resonances. We consider three resonance terms, which correspond to couplings to the s-, d-, and g-wave molecular states. Each term contains three parameters: Feshbach coupling strength \( \Gamma_i \), bare-state crossing position \( B_{c,i} \), and the relative magnetic moment \( \delta \mu_i \) [28]. All the parameters are evaluated by the fit. We assign the uncertainties of the parameters by a resampling method [29]. Second, we use the fitting parameters to determine \( a \) in the form of Eq. (12). Table I summarizes the main fit results for the three overlapping resonances. We derive the zeros and poles of the scattering length from Eqs. (12) and (14). Our results represent the most accurate knowledge of the positions and widths of the two experimental important resonances near 48 and 53 G [30,31].

Figure 4 shows the magnetic-field-dependent scattering length as derived from our model and the binding energy data. We observe a remarkable overall agreement between these results and a previous multichannel calculation based on knowledge of the positions of various Feshbach resonances [17]. Our present method proves particularly powerful for the scattering length near the two narrow resonances.

### Table I. Fitting parameters for the s-, d-, and g-wave Feshbach resonances, determining the scattering length in the magnetic-field range of interest; see Fig. 3. The background scattering length \( a_{bg} = 1875 a_B \), the mean scattering length of cesium, \( \bar{a} = 95.7 a_B \), and the bare s-wave state magnetic moment \( \delta \mu_1 = 2.50 \mu_B \) [28] are set constant. Poles \( B_{0,i} \) and zeros \( B^{*}_{i} \) of the scattering length are derived; see text. Uncertainties in the parentheses are statistical. The systematic uncertainty of the magnetic field is 10 mG.

Here the previous calculations [17] suffer from the large uncertainties of the positions of the resonances, which can even exceed their widths.

IV. CONCLUSION

In summary, we have described a method to precisely determine scattering lengths from binding energy measurements of weakly bound molecular states. We employ a simple interaction model to extract the relationship between the scattering length and the binding energy. Using the cesium molecule binding energy data in the range where three Feshbach resonances are present, we show that our model provides an excellent fit to the molecular energy structure near the resonances. Precise knowledge of the binding energy and scattering length near Feshbach resonances provides an ideal starting point to explore few- and many-body physics by controlling the two-body interactions. Our model is also general in the sense that it can apply to any homonuclear or heteronuclear atomic systems near Feshbach resonances, once molecular binding energy data are available.

[23] The optical trap is formed by a blue-detuned evanescent laser wave (wavelength 810 nm) on top of a horizontal glass prism. In addition, a red-detuned laser beam (wavelength 1060 nm, waist 80 μm), propagating along the vertical direction, confines the atoms in the horizontal plane.
[26] We use the Breit-Rabi formula to determine the magnetic-field value from a measurement of the resonant frequency corresponding to the $|F=3, m_F=3⟩ → |F=4, m_F=4⟩$ atomic hyperfine transition. Line noise limits the stability of the magnetic field to about 10 mG for typical integration times.
[28] The large uncertainty in fitting the $s$-wave state magnetic moment $\delta \mu_1$ leads to an instability of our fitting routine. We remove this instability by assigning $\delta \mu_1 = 2.5 \mu_0$ [19].
[29] We first form subsets of the measurement data (resampling),
and then perform the fitting routine. The uncertainties are assigned by analyzing the distribution of the resulting fit parameters. See, for example, P. H. Westfall and S. S. Young, *Resampling-Based Multiple Testing* (John Wiley and Sons, New York, 1993).
